### Purpose and Background of the Research

#### ●Outline of the Research

Smooth communication through language requires efficient mutual understanding and the maintenance of appropriate social relationships. However, mismatches often arise because knowledge of language use differs across individuals, even among native speakers. This research area aims to clarify, at a biologically grounded level, how mutual understanding is achieved between individuals with different linguistic knowledge. We approach language communication from the perspective of contact and fusion between different languages, using this framework to connect linguistics with primatology and neuroscience. In particular, we use pidgin languages that emerge through language contact as a simplified model of communication between individuals with different linguistic systems.

We focus on “tolerance” in communication and test the “tolerance-based language circuit hypothesis,” which proposes that neural mechanisms enabling the acceptance of variation support flexible and ambiguous human language. To address this, we compare social structure and communication diversity in primates and examine how exposure to different communication styles influences behavior and cognition. We combine comparative studies in primates with experimental approaches, including behavioral manipulation and neural intervention, to test these mechanisms.

Furthermore, we extend this work to a comparative neuroscience framework by focusing on brain regions shared between humans and monkeys. In particular, the anterior cingulate cortex (ACC) has been implicated in both semantic ambiguity and individual differences in tolerance. By manipulating neural activity in this region, we aim to reveal the causal relationship between tolerance and the diversification of communication.

### Expected Research Achievements

#### ●Achievements from Each Group

The three teams integrate approaches from behavior to neural circuits to test the “tolerance-based language circuit hypothesis,” proposing the co-evolution of tolerance and flexible communication.

#### Linguistics Team

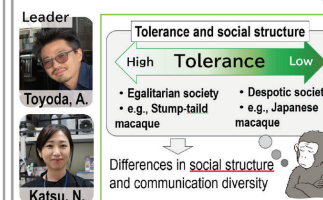

##### Human fMRI and speech analysis

We examine ambiguity in language and its neural representations through behavioral and brain data from neurotypical and neurodivergent individuals, and test how individual differences in language-use strategies relate to tolerance.

#### Primatology Team

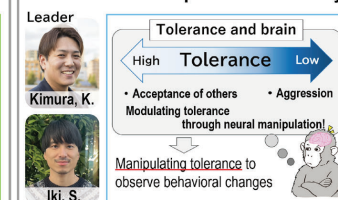

##### Field behavioral observation in monkeys

Using primate species with different levels of tolerance, we compare communication in the wild, conduct playback experiments, and analyze communication in hybrid zones between species.

#### Neuroscience Team

##### Neural circuit manipulation in monkeys

We combine primate behavioral paradigms with neural interventions to identify the neural basis of tolerance, focusing on ACC-centered circuits and their role in shaping communication patterns.

#### ●Broader Implications of the Research

Our goal is to advance a “tolerant hybrid society” in which diverse individuals interact and integrate. Building on our findings, we propose the hypothesis that human communication always occurs in hybrid zones and aim to establish a long-term interdisciplinary research field. By applying experimental approaches from the life sciences to linguistic models such as pidgin and creole, we seek to overcome key challenges in linguistics and develop a new cross-disciplinary framework. This work will clarify the co-evolution of tolerance and communication across cultural and developmental diversity, and expand into broader studies of cultural evolution. Led by an interdisciplinary team of early-career researchers, the project will also foster a dynamic research environment that promotes innovative thinking beyond traditional disciplinary boundaries.
